

An approach for evaluation of observables in analytic versions of QCD

Gorazd Cvetič and Cristián Valenzuela

Dept. of Physics, Universidad Técnica Federico Santa María, Valparaíso, Chile

(Dated: February 2, 2008)

We present two variants of an approach for evaluation of observables in analytic QCD models. The approach is motivated by the skeleton expansion in a certain class of schemes. We then evaluate the Adler function at low energies in one variant of this approach, in various analytic QCD models for the coupling parameter, and compare with perturbative QCD predictions and the experimental results. We introduce two analytic QCD models for the coupling parameter which reproduce the measured value of the semihadronic τ decay ratio. Further, we evaluate the Bjorken polarized sum rule at low energies in both variants of the evaluation approach, using for the coupling parameter the analytic QCD model of Shirkov and Solovtsov, and compare with values obtained by the evaluation approach of Milton *et al.* and Shirkov.

Consider an observable $\mathcal{O}(Q^2)$ depending on a single space-like scale $Q^2(\equiv -q^2) > 0$ and assume that the skeleton expansion for this observable exists:

$$\mathcal{O}_{\text{skel}}(Q^2) = \int_0^\infty \frac{dt}{t} F_{\mathcal{O}}^A(t) a_{\text{pt}}(te^C Q^2) + \sum_{n=2}^\infty s_{n-1}^{\mathcal{O}} \left[\prod_{j=1}^n \int_0^\infty \frac{dt_j}{t_j} a_{\text{pt}}(t_j e^C Q^2) \right] F_{\mathcal{O}}^A(t_1, \dots, t_n). \quad (1)$$

The observable is normalized such that $\mathcal{O}(Q^2) = a_{\text{pt}}$ at first order in perturbation theory. The characteristic functions $F_{\mathcal{O}}^A$ are symmetric functions and have the following normalization:

$$\int_0^\infty \frac{dt}{t} F_{\mathcal{O}}^A(t) = 1, \quad \int \frac{dt_1}{t_1} \frac{dt_2}{t_2} F_{\mathcal{O}}^A(t_1, t_2) = 1, \dots, \quad (2)$$

and $s_i^{\mathcal{O}}$ are the skeleton coefficients. The perturbative running coupling $a_{\text{pt}}(Q^2) \equiv \alpha(Q^2)/\pi$ obeys the renormalization group (RG) equation:

$$\frac{\partial a_{\text{pt}}(Q^2)}{\partial \log Q^2} = -[\beta_0 a_{\text{pt}}^2(Q^2) + \beta_1 a_{\text{pt}}^3(Q^2) + \dots]. \quad (3)$$

In QCD, the first two coefficients $\beta_0 = (1/4)(11 - 2n_f/3)$ and $\beta_1 = (1/16)(102 - 38n_f/3)$ are scheme-independent in mass-independent schemes; n_f is the number of active quarks flavors. The value of C depends on the value of the scale Λ in a_{pt} ($\Lambda_{(C)}^2 = \Lambda_{(0)}^2 e^C$) [1]. In $\overline{\text{MS}}$ scheme $C = \overline{C} \equiv -5/3$. The skeleton integrands and integrals are independent of C . Expansion (1) exists in QED if one excludes light-by-light subdiagrams [2, 3]. In the QCD case, the leading skeleton part was investigated in Refs. [1, 4]. We will assume that expansion (1) exists in a certain class of schemes.

On the other hand, the RG-improved perturbation expansion for the observable $\mathcal{O}(Q^2)$ is given by

$$\mathcal{O}_{\text{pt}}(Q^2) = a_{\text{pt}}(Q^2) + \sum_{n=2}^\infty c_{n-1} a_{\text{pt}}^n(Q^2). \quad (4)$$

Expanding $a_{\text{pt}}(te^C Q^2)$ around $t = e^{-C}$ inside the integrals in Eq. (1) must give Eq. (4).

The skeleton expansion is a reorganization of the perturbation series such that each term in (1) corresponds to the sum of an infinite number of Feynman diagrams. These sums, however, do not converge. Although it is possible to assign a value to these sums, this value is not unique, a renormalon ambiguity is present. In formulation (1) the ambiguities arise from the (nonphysical) Landau singularities of $a_{\text{pt}}(te^C Q^2)$ in the non-perturbative space-like region

¹ hep-ph/0601050v3 - one reference added; no other changes; version to appear in J. Phys. G.

$0 < Q^2 \leq \Lambda^2$ [1]. The difference between possible integration paths (prescriptions) is a measure of the size of the renormalon ambiguity.

The perturbative coupling is a solution of the n -loop RG equation (3). It can be found iteratively for $Q^2 \gg \Lambda^2$

$$a_{\text{pt}}(Q^2) = \sum_{i=1}^n \sum_{j=0}^{i-1} k_{ij} \frac{(\log L)^j}{L^i}, \quad (5)$$

where $L = \log(Q^2/\Lambda^2)$ and k_{ij} are constants depending on the β -function coefficients. At energies $Q \lesssim 1$ GeV the perturbative result (4), (5) is not reliable. At these energies a_{pt} starts being dominated by the Landau singularities at $0 < Q^2 \leq \Lambda^2$. These singularities are a consequence of the perturbative RG Eq. (3) and are located in the region where this equation is not valid. Furthermore, from general arguments (causality) [5] one concludes that the coupling parameter must be analytic in the whole Q^2 -plane excluding the time-like (Minkowskian) semiaxis. On this semiaxis, singularities associated with asymptotic states appear.

With this motivation it seems reasonable to replace the perturbative coupling by a new coupling $\mathcal{A}_1(Q^2)$ differing from $a_{\text{pt}}(Q^2)$ significantly only in the non-perturbative region and having the required analyticity properties. This replacement is not unique and should be considered as a phenomenological model. Using a dispersion relation, Shirkov and Solovtsov [5] proposed the following replacement:

$$a_{\text{pt}}(Q^2) \equiv \frac{1}{\pi} \int_{-\Lambda^2}^{\infty} \frac{d\sigma}{\sigma + Q^2} \rho_1(\sigma) \mapsto \mathcal{A}_1^{(\text{MA})}(Q^2) = \frac{1}{\pi} \int_0^{\infty} \frac{d\sigma}{\sigma + Q^2} \rho_1(\sigma), \quad (6)$$

where $\rho_1 = \text{Im}[a_{\text{pt}}(-\sigma - i\epsilon)]$, and a_{pt} is, e.g., given by Eq. (5).¹ We will refer to this as the minimal analytic (MA) procedure. In MA the discontinuity of the analytic coupling along the Minkowskian semiaxis is by construction the same as the one of a_{pt} .² Below we shall consider generalizations of this analytization procedure.

Once one analytizes $a_{\text{pt}}(Q^2)$ using Eq. (6) or other procedure, the question arises how to treat a known truncated perturbation series (TPS). For perturbation series (4) there is no unique way to analytize higher powers of a_{pt} . One possibility is to apply the MA procedure to each power of a_{pt} [10]:

$$a_{\text{pt}}^k(Q^2) \mapsto \mathcal{A}_k^{(\text{MA})}(Q^2) = \frac{1}{\pi} \int_0^{\infty} \frac{d\sigma}{\sigma + Q^2} \rho_k(\sigma) \quad (k = 1, 2, \dots), \quad (7)$$

where $\rho_k = \text{Im}[a_{\text{pt}}^k(-\sigma - i\epsilon)]$ and a_{pt} , e.g., is given by Eq. (5).³ Other choices could be, e.g., $a_{\text{pt}}^k \mapsto \mathcal{A}_1^k, \mathcal{A}_1^{k-2} \mathcal{A}_2$, etc. In this paper we propose a method to analytize a TPS based on the skeleton expansion (1), in any chosen version of QCD with analytic $\mathcal{A}_1(Q^2)$. In Eq. (1) the replacement $a_{\text{pt}} \mapsto \mathcal{A}_1$ is made, making the skeleton expansion terms well-defined integrals. Next, we Taylor-expand each $\mathcal{A}_1(t_j e^C Q^2)$ there around a specific $\ln Q_*^2 = \ln(t_* e^C Q^2)$. In these expansions, we denote

$$\widetilde{\mathcal{A}}_n(Q_*^2) \equiv \frac{(-1)^{n-1}}{\beta_0^{n-1} (n-1)!} \frac{\partial^{n-1} \mathcal{A}_1(Q_*^2)}{\partial (\ln Q_*^2)^{n-1}}, \quad (n = 2, 3, \dots) \quad (8)$$

If we know in expansion (4) TPS with $n_{\text{max}} = 3$ (i.e., c_1 and c_2), it is convenient to introduce the analytic couplings $\mathcal{A}_2$ and $\mathcal{A}_3$ according to

$$\begin{aligned} \widetilde{\mathcal{A}}_2(Q_*^2) &= \mathcal{A}_2(Q_*^2) + \frac{\beta_1}{\beta_0} \mathcal{A}_3(Q_*^2), \\ \widetilde{\mathcal{A}}_3(Q_*^2) &= \mathcal{A}_3(Q_*^2). \end{aligned} \quad (9)$$

When replacing here $\mathcal{A}_k \mapsto a_{\text{pt}}^k$, we obtain the corresponding truncated RG equations of perturbative QCD (pQCD). Thus, once one chooses a particular analytic coupling $\mathcal{A}_1$, the functions $\mathcal{A}_k$ with $k \geq 2$ are defined by Eqs. (9), or by a higher- n_{max} version thereof. In MA model (6), the results (7) and (9) merge when n_{max} increases [12] (cf. also [7]). In our approach, the basic set of functions is: $(\mathcal{A}_1$ and its derivatives $\widetilde{\mathcal{A}}_2, \widetilde{\mathcal{A}}_3, \dots)$. The set $(\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3, \dots)$ was introduced for the convenience of comparison with pQCD.

¹ An efficient method for evaluation of $\mathcal{A}_1^{(\text{MA})}$ was developed in Ref. [6]. A different evaluation of a_{pt} and ρ_1 was presented in Ref. [7].

² Other analytization procedures of a_{pt} focus on the analyticity properties of the beta function [8, 9].

³ An extension of Eq. (7) to noninteger powers was developed in Refs. [11].

The afore-mentioned Taylor-expansion around $\ln Q_*^2 = \ln(t_* e^C Q^2)$ for the order $n_{\max} = 3$ gives

$$\mathcal{A}_1(te^C Q^2) \approx \mathcal{A}_1(Q_*^2) - \beta_0 \ln(t/t_*) \widetilde{\mathcal{A}}_2(Q_*^2) + \beta_0^2 \ln^2(t/t_*) \widetilde{\mathcal{A}}_3(Q_*^2) \quad (10)$$

$$= \mathcal{A}_1(Q_*^2) - \beta_0 \ln(t/t_*) \mathcal{A}_2(Q_*^2) + [\beta_0^2 \ln^2(t/t_*) - \beta_1 \ln(t/t_*)] \mathcal{A}_3(Q_*^2). \quad (11)$$

Keeping terms corresponding to the third-order approximation we obtain a truncated analytic version of $\mathcal{O}(Q^2)$:

$$\begin{aligned} \mathcal{O}_{\text{tr}}^{(\text{an})}(Q^2) &= \mathcal{A}_1(Q_*^2) + [\beta_0 f_1^\mathcal{O}(t_*) \mathcal{A}_2(Q_*^2) + s_1^\mathcal{O} \mathcal{A}_1^2(Q_*^2)] \\ &\quad + [(\beta_0^2 f_2^\mathcal{O}(t_*) + \beta_1 f_1^\mathcal{O}(t_*)) \mathcal{A}_3(Q_*^2) + 2s_1^\mathcal{O} \beta_0 f_{1,0}^\mathcal{O}(t_*) \mathcal{A}_1(Q_*^2) \mathcal{A}_2(Q_*^2) + s_2^\mathcal{O} \mathcal{A}_1^3(Q_*^2)] , \end{aligned} \quad (12)$$

where $Q_*^2 \equiv t_* e^C Q^2$ and the momenta are

$$\begin{aligned} f_i^\mathcal{O}(t_*) &= \int_0^\infty \frac{dt}{t} F_\mathcal{O}^A(t) (-\log t/t_*)^i, \\ f_{i,j}^\mathcal{O}(t_*) &= \int \frac{dt_1}{t_1} \frac{dt_2}{t_2} F_\mathcal{O}^A(t_1, t_2) (-\log t_1/t_*)^i (-\log t_2/t_*)^j. \end{aligned} \quad (13)$$

Equation (12) is the result of the proposed analytization procedure for the series (4) truncated at $\sim a_{\text{pt}}^3$. In the perturbative region one has $\mathcal{A}_k \approx a_{\text{pt}}^k$ and Eqs. (12) and (4) merge. If $\mathcal{A}_1(Q^2)$ is well behaved at the origin then all $\mathcal{A}_k(Q^2)$ ($k \geq 2$) vanish at this point. This follows from the (truncated) RG-like Eqs. (9). Comparison between Eqs. (12) and (4) gives

$$\begin{aligned} c_1 &= \beta_0 f_1^\mathcal{O}(e^{-C}) + s_1^\mathcal{O}, \\ c_2 &= \beta_0^2 f_2^\mathcal{O}(e^{-C}) + \beta_1 f_1^\mathcal{O}(e^{-C}) + 2\beta_0 s_1^\mathcal{O} f_{1,0}^\mathcal{O}(e^{-C}) + s_2^\mathcal{O}. \end{aligned} \quad (14)$$

We assume that the skeleton expansion coefficients $s_j^\mathcal{O}$ and characteristic functions $F_\mathcal{O}^A(t_1, \dots, t_j)$ are n_f -independent when C is n_f -independent. Consequently, in the class of schemes where the coefficients c_j of expansion (4) are polynomials in n_f ($\leftrightarrow \beta_0$) of order j , relations (14) give us coefficients $s_1^\mathcal{O}$ and $s_2^\mathcal{O}$ and momenta $f_1^\mathcal{O}$, $f_2^\mathcal{O}$ and $f_{1,0}^\mathcal{O}$. We shall consider observables for which c_1 and c_2 are known. This approach can be continued to higher orders. The afore-mentioned class of schemes is parametrized by the RG β_j coefficients ($j \geq 2$) which are polynomials in n_f ($\leftrightarrow \beta_0$) of order j such that $\beta_j = b_{j0} + b_{j1}\beta_0 + \dots + b_{jj}\beta_0^j$, where $b_{j0} = \bar{b}_{j0}$ of $\overline{\text{MS}}$ scheme and b_{jk} ($k \geq 1$) are the free scheme parameters.

However, the knowledge of the perturbation coefficients c_j by itself is not enough to obtain the higher-order coefficients which are not included in Eq. (12). At fourth-order, the coefficients at $\mathcal{A}_2^2$ and $\mathcal{A}_1 \mathcal{A}_3$ cannot be obtained without certain assumptions for the characteristic function $F_\mathcal{O}^A(t_1, t_2)$ [12].

The leading characteristic function $F_\mathcal{O}^A(t)$ is known for many observables on the basis of their all-order large- n_f ($\leftrightarrow$ large- β_0) perturbation expansion [1, 13]. Therefore, we propose to keep the leading skeleton term unexpanded, but to expand the other terms as in Eq. (12)

$$\mathcal{O}_{\text{skel}}^{(\text{an})}(Q^2) = \int_0^\infty \frac{dt}{t} F_\mathcal{O}^A(t) \mathcal{A}_1(te^C Q^2) + s_1^\mathcal{O} \mathcal{A}_1^2(Q^2) + [s_2^\mathcal{O} \mathcal{A}_1^3(Q^2) + 2s_1^\mathcal{O} \beta_0 f_{1,0}^\mathcal{O}(t^{(2)}) \mathcal{A}_1(Q^2) \mathcal{A}_2(Q^2)], \quad (15)$$

where we used two different expansion scales for the NL and NNL skeleton terms: $Q_2^2 \equiv t^{(2)} e^C Q^2$ and $Q_3^2 \equiv t^{(3)} e^C Q^2$, respectively. Since $f_{1,0}^\mathcal{O}(t^{(2)}) = f_{1,0}^\mathcal{O}(e^{-C}) + \ln t^{(2)} + C$ and $f_{1,0}^\mathcal{O}(e^{-C})$ is known, it is convenient to use a scale of the BLM type [3, 14]: $t^{(2)} = t_*^{(2)} \equiv \exp(-C - f_{1,0}^\mathcal{O}(e^{-C}))$ such that $f_{1,0}^\mathcal{O}(t_*^{(2)}) = 0$. Consequently, the $\mathcal{A}_1 \mathcal{A}_2$ term in Eq. (15) disappears. Further, the scheme dependence at this level shows up as the dependence of $s_2^\mathcal{O}$ and $t_*^{(2)}$ on b_{21} and b_{22} , respectively [12]. This allows us to fix the latter two coefficients, for each specific observable, in such a way that $s_2^\mathcal{O} = 0$ and, e.g., $t_*^{(2)} = 1$. For example, if the starting scheme is $\overline{\text{MS}}$ ($\bar{b}_{21}$, $\bar{b}_{22}$, and $\bar{C} \equiv -5/3$), the new scheme coefficients b_{2j} are

$$\begin{aligned} b_{21} &= \bar{b}_{21} + \bar{c}_{20} + \frac{107}{16} \bar{c}_{11}, \\ b_{22} &= \bar{b}_{22} + \bar{c}_{21} - \frac{19}{4} \bar{c}_{11} + 2\bar{C} \bar{c}_{10}, \end{aligned} \quad (16)$$

where $\bar{c}_{jk}$ are expansion coefficients of the perturbation coefficient c_j , Eq. (4), in powers of β_0 , in $\overline{\text{MS}}$ scheme: $\bar{c}_j = \sum_0^j \bar{c}_{jk} \beta_0^k$. In the scheme (16), the skeleton-based expansion (15) reduces to

$$\mathcal{O}_{\text{v1}}^{(\text{an})}(Q^2) = \int_0^\infty \frac{dt}{t} F_\mathcal{O}^A(t) \mathcal{A}_1(te^C Q^2) + s_1^\mathcal{O} \mathcal{A}_1^2(e^C Q^2) + \mathcal{O}_n, \quad (17)$$

where $\mathcal{O}_n = \mathcal{O}_4$ are now formally terms of fourth order ($\sim \mathcal{A}_1^4, \mathcal{A}_1^2 \mathcal{A}_2, \dots$). We will call formula (17) the first variant (“v1”) of our skeleton-motivated evaluation approach. Adopting the scheme (16), or higher order generalizations of it, higher order contributions are absorbed in the two terms of Eq. (17). This scheme-fixing method is particularly useful at low energies where scheme dependence is important.

The skeleton QCD expansion, if it exists, is probably valid only in a specific (yet unknown) “skeleton” scheme [3, 4]. A possible difference between the latter and the schemes used here will result in a difference in the evaluation of the observable $\mathcal{O}(Q^2)$. This difference, when re-expanded in a_{pt} , is at most $\sim a_{\text{pt}}^4$ subleading- β_0 (i.e., $\sim \beta_0^2 a_{\text{pt}}^4$).

The derivation up until now allows us to present yet another variant (“v2”) of the evaluation approach, by keeping the scheme (16) and simply replacing $\mathcal{A}_1^2(e^C Q^2)$ by $\mathcal{A}_2(e^C Q^2)$ in Eq. (17)

$$\mathcal{O}_{\text{v2}}^{(\text{an})}(Q^2) = \int_0^\infty \frac{dt}{t} F_{\mathcal{O}}^{\mathcal{A}}(t) \mathcal{A}_1(te^C Q^2) + s_1^{\mathcal{O}} \mathcal{A}_2(e^C Q^2) + \mathcal{O}_n, \quad (18)$$

This formula can be obtained by repeating the previous derivation, but starting with the skeleton expansion (1) without the analytization replacements $a_{\text{pt}} \mapsto \mathcal{A}_1$ there. All the expansions are then obtained as previously, but with a_{pt}^n instead of $\mathcal{A}_n$, $\mathcal{A}_{n-1} \mathcal{A}_1$, etc. In this variant, the analytization is performed at the end, by replacing $a_{\text{pt}} \mapsto \mathcal{A}_1$ in the leading-skeleton integral, and replacing $a_{\text{pt}}^2 \mapsto \mathcal{A}_2$ in the term proportional to $s_1^{\mathcal{O}}$, leading to Eq. (18).

We wish to stress that neither variant of the evaluation approach relies on the existence of the skeleton expansion. Our derivation can be interpreted in the following alternative way: The formal skeleton expansion (1) provides us with the tools to separate the perturbation series of the observable into several perturbation subseries. The first subseries (from the leading skeleton term) includes all the leading- β_0 terms, the second subseries (from the subleading skeleton term) includes all the leading- β_0 terms of the rest, etc. Each of these perturbation subseries is renormalization scale invariant. A specific renormalization scheme ($\beta_2, \beta_3, \dots$) is then found such that all the perturbation subseries vanish, except the first two. In the end, the analytization of the two surviving subseries is performed.

If the perturbation coefficient c_3 is known, then the entire described procedure can be carried out to one higher order, i.e., the β_3 -coefficients b_{3j} ($j = 1, 2, 3$) can be determined so that in Eqs. (17)-(18) $\mathcal{O}_n = \mathcal{O}_5$ ($\sim \mathcal{A}_1^5, \mathcal{A}_1^3 \mathcal{A}_2, \dots$), under certain assumptions for the function $F_{\mathcal{O}}^{\mathcal{A}}(t_1, t_2)$ [12]. For example, for the massless Adler function, the $\bar{\tau}_3$ coefficient has been estimated as a polynomial in n_f to a high degree of accuracy [15], and the scheme can be found such that in Eqs. (17)-(18) $\mathcal{O}_n = \mathcal{O}_5$. Of course, the higher order analytic couplings $\mathcal{A}_n$ ($n \geq 2$) are defined in this case by the $n_{\text{max}} = 4$ extension of Eqs. (9)

$$\begin{aligned} \widetilde{\mathcal{A}}_2(Q_*^2) &= \mathcal{A}_2(Q_*^2) + \frac{\beta_1}{\beta_0} \mathcal{A}_3(Q_*^2) + \frac{\beta_2}{\beta_0} \mathcal{A}_4(Q_*^2), \\ \widetilde{\mathcal{A}}_3(Q_*^2) &= \mathcal{A}_3(Q_*^2) + \frac{5}{2} \frac{\beta_1}{\beta_0} \mathcal{A}_4(Q_*^2), \\ \widetilde{\mathcal{A}}_4(Q_*^2) &= \mathcal{A}_4(Q_*^2), \end{aligned} \quad (19)$$

and expansion of $\mathcal{A}_1(te^C Q^2)$ is now performed up to and including $\widetilde{\mathcal{A}}_4(Q_*^2)$, in contrast to Eq. (10).

In practical evaluations, the form of the analytic coupling parameter $\mathcal{A}_1(Q^2)$ has to be specified. The most straightforward is the minimal analytic (MA) coupling (6). The latter model gives the value $\bar{\Lambda} \equiv \Lambda_{(C=-5/3)} \approx 0.4$ GeV (in $\overline{\text{MS}}$ and with $n_f = 3$) from fitting high energy QCD observables [16]. However, in order to reproduce the measured value of the semihadronic tau decay ratio r_τ , it requires introduction of heavy first generation quark masses $m_u \approx m_d \approx 0.25$ GeV [10]. Another possibility would be to modify the MA-coupling at low energies, e.g., in the following manner

$$\mathcal{A}_1^{(M1)}(Q^2) = c_f \frac{M_r^2 Q^2}{(Q^2 + M_r^2)^2} + k_0 \frac{M_0^2}{(Q^2 + M_0^2)} + \frac{Q^2}{(Q^2 + M_0^2)} \frac{1}{\pi} \int_{\sigma=M_0^2}^\infty \frac{d\sigma \rho_1(\sigma)(\sigma - M_0^2)}{\sigma(\sigma + Q^2)}. \quad (20)$$

In this “M1” model, k_0 , c_f , $c_0 = M_0^2/\Lambda^2$, and $c_r = M_r^2/\Lambda^2$ are four dimensionless and C -independent parameters which determine the low energy modification of the coupling (a special case, $k_0 = -1$, of M1 was presented in Ref. [17]). In general, at high energies, this coupling differs from the MA-coupling by $\sim \bar{\Lambda}^2/Q^2$. However, requiring that the difference be only $\sim \bar{\Lambda}^4/Q^4$ fixes parameter k_0 in terms of the other three. Consequently, $\bar{\Lambda} \approx 0.4$ GeV from fitting to high energy QCD observables, as in the MA case. The remaining three parameters can be fixed by requiring that the experimental value of r_τ and some other low energy observable, e.g., Bjorken polarized sum rule $d_b(Q^2)$, be reproduced by the afore-mentioned procedure. The experimental values of these two observables are $r_\tau = 0.196 \pm 0.010$ [18] and $d_b(Q^2) = 0.16 \pm 0.11$ at $Q^2 = 2$ GeV² [19], where the normalization was chosen such that $r_\tau = a_{\text{pt}} + \mathcal{O}(a_{\text{pt}}^2)$ and similarly for d_b . The quark mass effects are subtracted (not contained) here.

The use of the MA-coupling, in our approach (16)-(17) and with massless first three quarks and $\bar{\Lambda} = 0.4$ GeV, gives $d_b(Q^2 = 2.) \approx 0.13$ in v1 (0.14 in v2) which is acceptable, and $r_\tau = 0.140$ in v1 (0.139 in v2) which is not acceptable.⁴ If we require, in model M1, the reproduction of $r_\tau \approx 0.196$ and $d_b(Q^2 = 2.) \approx 0.13 - 0.14$, in the evaluation approach v1, with massless quarks, and $\bar{\Lambda} = 0.4$ GeV, we obtain for the choice $c_0 = 2$ the values of $c_r \approx 0.5$ and $c_f \approx 1.7$. Changing c_0 while keeping it ~ 1 gives us by the same procedure different values of c_r and c_f to reproduce the afore-mentioned values of r_τ and d_b . In such cases, yet another low energy observable, the (massless) Adler function, remains quite stable under the variation of c_0 . In M1 we will take $c_0 = 2$, $c_r = 0.5$, $c_f = 1.7$ (and $\bar{\Lambda} = 0.4$ GeV). With these parameter values: v1 approach (17) gives $r_\tau = 0.197$ (0.202 when $\mathcal{O}_n = \mathcal{O}_4$ for $d(m_\tau^2 e^{i\theta})$ in Eq. (17)) and $d_b(Q^2 = 2.) \approx 0.14$; v2 approach (18) gives $r_\tau = 0.210$ (0.201 when $\mathcal{O}_n = \mathcal{O}_4$) and $d_b(Q^2 = 2.) \approx 0.14$.

Yet another, simpler, modification of the MA-model is

$$\mathcal{A}_1^{(M2)}(Q^2) = \mathcal{A}_1^{(\text{MA})}(Q^2) + \tilde{c}_v \frac{\tilde{M}_0^2}{Q^2 + \tilde{M}_0^2}. \quad (21)$$

In this “M2” model,⁵ we will take the parameter values $\tilde{c}_v = 0.2$, $\tilde{c}_0 \equiv \tilde{M}_0^2/\Lambda^2 \approx 0.56$ and $\bar{\Lambda} = 0.4$ GeV. With these values, v1 approach (17) gives $r_\tau = 0.188$ (0.194 when $\mathcal{O}_n = \mathcal{O}_4$) and $d_b(Q^2 = 2.) \approx 0.18$; v2 approach (18) gives $r_\tau = 0.188$ (0.193 when $\mathcal{O}_n = \mathcal{O}_4$) and $d_b(Q^2 = 2.) \approx 0.19$.

Having fixed the parameters in the afore-mentioned models M1 and M2, we present in Fig. 1 low energy results of the Adler function $d(Q^2)$ associated with the hadronic part of the electromagnetic current, in the models MA, M1 and M2 (for a different evaluation of $d(Q^2)$, cf. [23]). The normalization was taken again such that in the massless quark limit for $n_f = 3$: $d(Q^2) = a_{\text{pt}} + \mathcal{O}(a_{\text{pt}}^2)$. The lower curves in Fig. 1 represent the results of the v1-evaluation (17) with three massless quarks, in the scheme where $\mathcal{O}_n = \mathcal{O}_5$. The higher curves represent the full quantity, i.e., the effects of the massive c and b quarks are added, with the coefficients as given in Ref. [24] ($d(Q^2) = (1/2)D(Q^2) - 1$, where D is defined in [24]). In the contributions of c and b , we simply replaced $a_{\text{pt}}(Q^2)$ and $a_{\text{pt}}^2(Q^2)$ by $\mathcal{A}_1(Q^2)$ and $\mathcal{A}_2(Q^2)$, and used $\Lambda = \bar{\Lambda}$ ($C = -5/3$). $\mathcal{A}_2(Q^2)$ was constructed by the fourth-order relations (19). The indicated $\pm$ uncertainties in these curves are those charm contributions which are $\propto \mathcal{A}_2(Q^2)$. In contrast to the massless contributions, we do not have yet a systematic way to analytize the massive quark contributions. The experimental results [24] and the truncated pQCD series were included for comparison. Figure 1 shows that analytic versions of QCD (MA, M1, M2) in conjunction with the skeleton-motivated approach (17) give results that at low energies $Q \sim 1$ GeV behave much better than pQCD.

Application of variant 2 of our approach, Eq. (18), gives for the Adler function results which are very close to those of variant 1, Eq. (17), because the coefficient $s_1^\mathcal{O}$ is small: $s_1^\mathcal{O} = 1/12$. For the Bjorken polarized sum rule $d_b(Q^2)$, this is not so, because $s_1^\mathcal{O} = -11/12$ is appreciable. Therefore, we will take the Bjorken sum rule as a case to look at numerical differences between evaluations in our approaches v1 and v2, Eqs. (17)-(18). In addition, we will compare with the approach of Milton *et al.* and Shirkov [10, 16] (MSSSh)

$$\mathcal{O}_{\text{MSSSh}}(Q^2) = \mathcal{A}_1(Q^2) + c_1 \mathcal{A}_2(Q^2) + c_2 \mathcal{A}_3(Q^2). \quad (22)$$

In principle, the comparison between the approaches can be carried out in any analytic QCD model for the coupling parameter. However, the MSSSh approach has been applied in the literature in the MA model. Therefore, we carry out the comparison in this model. In Fig. 2 we present the MA-model predictions for $d_b(Q^2)$, with various evaluations, at third order [$\mathcal{O}_n = \mathcal{O}_4$ in Eqs. (17)-(18)]. The results of the MSSSh approach are presented in two schemes: $\overline{\text{MS}}$ (“bMS”); and in the “b2Sk” scheme where β_2 is determined by Eqs. (16) for d_b . The MSSSh approach uses the three-loop MA-expressions $\mathcal{A}_2(Q^2)$ and $\mathcal{A}_3(Q^2)$ of Eq. (7) (Refs. [10, 16]), and variant 2 of our approach, Eq. (18), uses $\mathcal{A}_2(Q^2)$ from Eqs. (9). Figure 2 shows that the evaluation of $d_b(Q^2)$ with variant 1 of our approach Eq. (17) (“Sk v1 b2Sk”) gives, at low energies, results which differ significantly from the MSSSh approach. On the other hand, variant 2 of our approach (“Sk v2 b2Sk”), i.e., Eq. (18), gives results which are, apparently accidentally, very close to those of the MSSSh approach in the $\overline{\text{MS}}$ scheme.

In summary, we presented two variants of skeleton-expansion-motivated evaluation of observables in analytic versions of QCD, Eqs. (17)-(18). The first variant follows more closely the skeleton expansion, in the sense that the analytization

⁴ For the corresponding massless Adler function $d(Q^2)$ we use the scheme where in Eqs. (17)-(18) $\mathcal{O}_n = \mathcal{O}_5$ [12]. If taking a scheme with by one order lower precision ($\mathcal{O}_n = \mathcal{O}_4$, $\beta_3 \mapsto 0$), the value changes to $r_\tau = 0.146$ in v1 (0.145 in v2). Observable r_τ is evaluated by first evaluating the Adler function $d(Q^2)$ for complex values $Q^2 = m_\tau^2 e^{i\theta}$ and then applying the standard contour integration in the Q^2 -plane. The function $F_\mathcal{O}^A(t)$ for $d(Q^2)$ was obtained in Ref. [1]. $F_\mathcal{O}^A(t)$ for $d_b(Q^2)$ can be obtained from the known large- n_f expansion of $d_b(Q^2)$ [20], using the technique of Ref. [1], and the full perturbation coefficients c_1 and c_2 from [21].

⁵ In Ref. [22], power correction terms $1/(Q^2)^n$ were added to $\mathcal{A}_1^{(\text{MA})}(Q^2)$, but with a somewhat different motivation.

is performed at the beginning, in the skeleton expansion ($a_{\text{pt}} \mapsto \mathcal{A}_1$). In the second variant, the analytization is performed at the end, in the form $a_{\text{pt}}^k \mapsto \mathcal{A}_k$. The second variant can be regarded as a generalization of the evaluation approach of Milton *et al.* and Shirkov [10, 16] (MSSSh), now including the leading- β_0 terms to all orders in the coupling parameter. Both variants use the formal structure of the skeleton expansion in order to divide the original perturbation expansion into a sum of subseries (skeleton terms), each of them renormalization scale invariant, and then using a scheme where only the first two subseries survive. Further, we introduced two alternative models (M1, M2) of analytic QCD for the coupling parameter which, for certain values of the model parameters, reproduce the measured values of the semihadronic τ decay ratio.
